Computing the Distribution of a Tree Metric

David Bryant and Mike Steel

Abstract—The Robinson-Foulds (RF) distance is by far the most widely used measure of dissimilarity between trees. Although the distribution of these distances has been investigated for 20 years, an algorithm that is explicitly polynomial time has yet to be described for computing the distribution for trees around a given tree. In this paper, we derive a polynomial-time algorithm for this distribution. We show how the distribution can be approximated by a Poisson distribution determined by the proportion of leaves that lie in “cherries” of the given tree. We also describe how our results can be used to derive normalization constants that are required in a recently proposed maximum likelihood approach to supertree construction.

Index Terms—Biology and genetics, discrete mathematics applications, trees, phylogenetics, Robinson-Foulds distance, Poisson approximation, normalization constant.

1 INTRODUCTION

Tree comparison metrics are widely used in phylogenetics for comparing evolutionary trees [3], [9] and performing statistical tests—for example, to test whether two trees are more “significantly different” from each other than one might expect if one or both trees were randomly chosen [6], [7]. In order to address these statistical questions, one needs to determine the distribution of the metric under some null model (see, for example, [6], [7]). The symmetric difference or Robinson-Foulds metric is the most widely used measure of differences between phylogenetic trees, and its distribution is particularly attractive to study. In a landmark paper [4], the authors described this distribution of trees relative to a fixed reference tree via a system of generating functions. This allowed the authors to calculate the distribution explicitly for small trees and provided a tool for analytic results on this distribution in later work by others.

However, the approach described in [4] does not immediately appear to provide a polynomial-time algorithm for computing this distribution, and for larger trees, their approach may be computationally prohibitive. In this paper, we describe how to calculate the distribution of the Robinson-Foulds metric relative to a fixed tree. We also show how the distribution can be approximated by a Poisson distribution whose parameter depends on just one aspect of tree shape—the number of “cherries.”

Our investigation into the distribution of the metric has also been motivated by its relevance to a recent approach for “supertree” construction that is based on maximum likelihood [12]. In particular, our algorithm allows the normalization constants in the likelihood calculations to be computed explicitly. We describe how these normalization constants depend weakly on aspects of the shape of the tree—for example, how many “cherries” the tree has. We start by recalling some terminology.

1.1 Terminology

Let $X$ be a finite set. A phylogenetic tree with leaf set $X$ is a tree with its degree 1 vertices (leaves) labeled bijectively by elements of $X$ and whose remaining vertices have degree at least 3. We use $V(T)$ and $E(T)$ to denote the set of nodes (vertices) and edges of $T$. Let $\bar{V}(T)$ denote the set of internal (nonleaf) nodes of $T$ and $\bar{E}(T)$ be the set of edges in $E(T)$ that have both endpoints in $\bar{V}(T)$, the internal edges.

A phylogenetic tree is fully resolved if every internal vertex has degree 3. Following [4], we let $PT(n)$ denote the set of phylogenetic trees on the finite set $X = \{1, 2, \ldots, n\}$ and $BPT(n)$ the set of fully resolved (“binary”) trees in $PT(n)$ (two trees in $BPT(6)$ are shown in Fig. 1). The number of trees in $BPT(n)$ is denoted $b(n)$ and is given by

$$b(n) = (2n - 5)!! = \prod_{k=3}^{n}(2k - 5) \quad n \geq 3,$$

see [9]. For convenience, we let $\beta(m)$ denote the number of fully resolved trees with exactly $m$ internal edges, so

$$\beta(m) = b(m + 3) = \prod_{k=3}^{m+3}(2k - 5) \quad m \geq 0.$$

Every edge $e \in E(T)$ induces a bipartition or split of the leaf set $X$ corresponding to the labels present in the two connected components remaining when the edge $e$ is removed. Let $\pi(T, e)$ denote this bipartition, which we consider unordered. We let $c(T)$ denote the set of all bipartitions obtained by removing different edges of $T$. Hence, $|c(T)| \leq 2n - 3$, the maximum number of edges in a phylogenetic tree, and $|c(T)| = 2n - 3$ exactly when $T$ is fully resolved. A bipartition is trivial if it separates a single element from all other elements; trivial bipartitions correspond to the edges in the tree that are external, meaning that they are incident with a leaf of the tree. A cherry of a fully resolved phylogenetic tree $T$ is a pair of leaves that forms...
Define the polynomial
\[ q(T, x) = \sum_{s=0}^{n-3} q_s(T) x^s. \] (4)

Let \( E \subset \hat{E}(T) \) denote a subset of the set of internal edges of \( T \). The forest \( T - E \) has exactly \(|E| + 1\) components \( F_1, F_2, \ldots, F_{|E|+1} \). We use \( \hat{E}(F) \) as a short hand for the edges of \( \hat{E}(T) \) that are contained in \( F \).

Define
\[ N_E(T) = \prod_{i=1}^{|E|+1} \beta(|\hat{E}(F_i)|). \] (5)

Note that \( N_E(T) \) equals the quantity \( \langle \Phi(E) \rangle \) defined in [10] (here, assuming that \( T \) is fully resolved) and also equals the number of fully resolved trees containing all those splits induced by edges in \( E \).

For \( s \geq 0 \), define
\[ r_s(T) = \sum_{|E|=s} N_E(T), \]
the sum of \( N_E \) over all subsets \( E \subseteq \hat{E}(T) \) of cardinality \( s \). For example, \( r_0(T) \) equals \( \beta(|\hat{E}(T)|) = \beta(n - 3) \). It was shown in [10] that the generating function
\[ R(T, x) = \sum_{s \geq 0} r_s(T) x^s \] satisfies the identity
\[ q(T, x) = R(T, x - 1). \] (6)

In what follows, we derive a formula to evaluate the coefficients \( r_s(T) \) so that we can compute the coefficients \( b_m(T) \) via (3) and (6).

As usual, the computation applies dynamic programming, requiring us to introduce definitions for the appropriately divided subproblems. Let \( v_0 \) be the node adjacent to leaf \( n \). Delete leaf \( n \) and make \( v_0 \) the root of the tree so that now every internal node has exactly two children. For each internal node \( v \), let \( T_v \) denote the subtree of \( T \) containing \( v \) and all of its descendants. Given a subset \( E \subseteq \hat{E}(T_v) \), we define \( N_E(T_v) \) as in (5), where \( F_1, \ldots, F_{|E|+1} \) will now be components of \( T_v - E \) instead of \( T - E \). We let \( \kappa(v, E) \) denote the number of edges in the component of \( T_v - E \) containing \( v \). For \( s, k \geq 0 \), we let \( \mathcal{E}(v, s, k) \) denote the set of all subsets \( E \subseteq \hat{E}(T_v) \) such that \(|E| = s \) and \( \kappa(v, E) = k \). Define
\[ R(v, s, k) = \sum_{E \in \mathcal{E}(v, s, k)} N_E(T_v). \] (7)
so that if \( v_0 \) is the root of \( T \) and \( s \geq 0 \), we have
\[ r_s(T) = \sum_{k=0}^s R(v_0, s, k). \] (8)

With these definitions in mind, and recalling the notation \( \beta(m) \) from (2), we now derive a recursion for \( R(v, s, k) \). As is customary, an empty summation equals zero.

---

2 Computing the Distribution of the Robinson-Foulds Metric

For each \( T \in PT(n) \), let \( b_m(T) \) denote the number of trees \( T' \in BPT(n) \) for which \( d(T, T') = m \). As \( d \) is a metric, \( b_0(T) = 1 \). A recursive formula for the generating function of \( b_m(T) \) is given in [4] and [10]. This formula can be described conveniently using generating functions. Let
\[ B(T, x) := \sum_{m \geq 0} b_m(T)x^m. \]

For any interior edge \( e \) of \( T \), let \( T/e \) be the tree formed by contracting \( e \), and let \( T_1, T_2 \) be the maximal subtrees of \( T \) with \( e \) as a pendant edge. Then, from [4], we have
\[ B(T, x) = xB(T/e, x) + (1 - x^2)B(T_1, x)B(T_2, x). \]
As far as we could deduce, the recursion described by this generating function identity does not provide a polynomial-time algorithm for computing the \( b_m(T) \) values, due to an exponential explosion in the number of subcases.

Instead, we use an alternative approach, applying results of [10]. Let \( q_s(T) \) denote the number of trees in \( BPT(n) \) that share exactly \( s \) internal splits with \( T \). Then, for all \( m = 0, 2, 4, \ldots, 2(n-3) \), we have
\[ b_m(T) = q_{n-3-m/2}(T). \] (3)

The metric was introduced by Bourque [1] and generalized by Robinson and Foulds [8]. As all phylogenetic trees contain all trivial splits, the maximum possible distance between two trees is \( 2(n - 3) \), which is twice the maximum number of internal edges.

---

Fig. 1. Two fully resolved phylogenetic trees on six leaves, with Robinson-Foulds distance value of 2.
Lemma 1. Suppose that \( v \in \bar{V}(T) \). Then,
\[
R(v, 0, k) = \begin{cases} 
\beta(k) & \text{if } k = |\bar{E}(T_v)|, \\
0 & \text{otherwise}.
\end{cases}
\] (9)

Lemma 2. Suppose that \( s \geq 1 \). For all \( v \in \bar{V}(T) \), let \( n_v = |\bar{E}(T_v)| \).

1. If \( k > n_v \), then \( R(v, s, k) = 0 \).
2. If \( v \in \bar{V}(T) \) has no children in \( \bar{V} \) and \( s \geq 1 \), then \( R(v, s, k) = 0 \).
3. If \( v \in \bar{V}(T) \) has one child \( v_1 \) in \( \bar{V} \), then
\[
R(v, s, k) = \begin{cases} 
\sum_{k_1=0}^{k} R(v_1, s, k_1) & \text{if } k = 0, \\
R(v_1, s, k-1)(2k + 1) & \text{otherwise}.
\end{cases}
\] (10)

4. If \( v \in \bar{V}(T) \) has two children \( v_1, v_2 \) in \( \bar{V}(T) \), then
\[
R(v, s, 0) = \sum_{s_1=0}^{s-2} \left( \sum_{k_1=0}^{s_1} R(v_1, s_1, k_1) \right) \left( \sum_{k_1=0}^{s-2-s_1} R(v_2, s-2-s_1, k_2) \right).
\] (11)

5. If \( v \in \bar{V}(T) \) has two children \( v_1, v_2 \) in \( \bar{V}(T) \) and \( k \geq 1 \), then
\[
R(v, s, k) = \sum_{s_1=0}^{s-1} \left( \sum_{k_1=0}^{s_1} R(v_1, s_1, k_1) \right) R(v_2, s-1-s_1, k-1) / \beta(k) / \beta(k-1) + \sum_{s_1=0}^{s-1} \left( \sum_{k_2=0}^{k-2} R(v_2, s_2, k_2) \right) R(v_1, s_1, s_2, k_1) / \beta(k) / \beta(k-1) + \sum_{s_1=0}^{s-2} \sum_{k_1=0}^{k-2} R(v_1, s_1, k_1) R(v_2, s-s_1, k-2-k_1) / \beta(k) / \beta(k-1) / \beta(k_1) / \beta(k-2-k_1). \] (12)

**Proof.** Parts 1 and 2 follow from the definition of \( R \).

3. Let \( e \) be the edge from \( v_1 \) to \( v \). When \( k = 0 \), it holds that \( E \in \mathcal{E}(v, s, k) \) if and only if \( E = E_1 \cup \{e\} \) for some \( E_1 \in \mathcal{E}(v_1, s_1, k_1) \), where \( k_1 \) ranges from 0 to \( s-1 \). This gives the first case. When \( k \geq 1 \), the edge \( e \) connecting \( v \) and \( v_1 \) is absent from every set in \( \mathcal{E}(v, s, k) \). Thus, \( E \in \mathcal{E}(v, s, k) \) if and only if \( E \in \mathcal{E}(v_1, s_1, k_1-1) \):
\[
N_E(T_v) = N_E(T_{v_1}) \beta(k) / \beta(k-1) = N_E(T_{v_1})(2k + 1).
\]

4. Let \( e_1, e_2 \) be the edges from \( v \) to \( v_1, v_2 \), respectively. Since \( k = 0 \), for all \( E \in \mathcal{E}(v, s, k) \), we have \( e_1 \in E \) and \( e_2 \in E \). Thus, \( E \in \mathcal{E}(v, s, k) \) if and only if there exists \( E_1 \in \mathcal{E}(v_1, s_1, k_1) \) and \( E_2 \in \mathcal{E}(v_2, s - 2 - s_1, k_2) \) for some \( s_1, k_1, k_2 \geq 0 \) such that \( E = E_1 \cup E_2 \). For each such set \( E \), we have:
\[
N_E(T_v) = N_E(T_{v_1}) N_E(T_{v_2}) \beta(k) / \beta(k-1). \]

5. Again, let \( e_1, e_2 \) be the edges from \( v \) to \( v_1, v_2 \), respectively. For each \( E \in \mathcal{E}(v, s, k) \) with \( k > 0 \), exactly one of the following cases holds:

**Case 1.** \( e_1 \in E \) but \( e_2 \notin E \). This case applies if and only there exists \( E_1 \in \mathcal{E}(v_1, s_1, k_1) \) and \( E_2 \in \mathcal{E}(v_2, s - 1 - s_1, k-1) \) for some \( s_1, k_1 \geq 0 \) such that \( E = E_1 \cup E_2 \). For each such set \( E \), we have
\[
N_E(T_v) = N_E(T_{v_1}) N_E(T_{v_2}) \beta(k) / \beta(k-1). \]

**Case 2.** \( e_1 \notin E \) but \( e_2 \in E \). Identical to Case 1 with \( v_1 \) and \( v_2 \) switched.

**Case 3.** \( e_1 \notin E \) and \( e_2 \notin E \). This case applies if and only there exists \( E_1 \in \mathcal{E}(v_1, s_1, k_1) \) and \( E_2 \in \mathcal{E}(v_2, s - 1, k - 1, k_2 - 2) \) such that \( E = E_1 \cup E_2 \). For each such set \( E \), we have
\[
N_E(T_v) = N_E(T_{v_1}) N_E(T_{v_2}) \beta(k) / \beta(k_1) / \beta(k-2-k_1). \]

**Theorem 3.** Given a fully resolved tree \( T \) on \( n \) leaves, the coefficients \( b_m(T) \) can be computed in \( O(n^3) \) time.

**Proof.** Consider a vertex \( v \in \bar{V}(T) \). If \( v \) has one child in \( \bar{V}(T) \), then we evaluate (10) for all \( s, k \leq n - 3 \) in \( O(n^3) \) time. If \( v \) has two children in \( \bar{V}(T) \), then we evaluate (12) in \( O(n^3) \) time.

Hence, computing all the coefficients \( r_s(T) \) takes \( O(n^3) \) time. From (6), we obtain
\[
q_m(T) = \sum_{s=m}^{n-3} \binom{s-1}{m} r_s(T)(-1)^s - m, \] (13)

from which we compute the values \( b_m(T) = q_{n-3-m/2}(T) \).

**3 Poisson Approximation**

When \( n \) is large, we can approximate the \( q_s(T) \) values by a Poisson distribution with mean \( \lambda_T := c_T / 2n \), where \( c_T \) denotes the number of cherries of \( T \) (recall that a cherry is a pair of leaves whose incident edges contain a common vertex). More precisely, we have the following result.

**Theorem 4.** For any tree \( T \in BPT(n) \), let \( Y_T \) be a Poisson random variable with mean \( \lambda_T \). Then, the distribution \( q_s(T) / b(n) \) as a function of \( s \) (the proportion of trees in \( BPT(n) \) that share \( s \) nontrivial splits with \( T \)) and the distribution of \( Y_T \) have variational distance that converges to zero as \( n \to \infty \). In particular,
\[
\sum_{s=0}^{\infty} \left| q_s(T) / b(n) - e^{-\lambda_T} \lambda_T^s / s! \right| = O(n^{-1} \).
Proof. Let $X_T$ denote the random variable which counts the number of nontrivial splits that $T$ shares with a tree $T'$ selected uniformly at random from $BPT(n)$. Thus, $\mathbb{P}(X_T = s) = g_s(T)/b(n)$. Let $X_T'$ be defined in the same ways as for $X_T$ but counting only splits that divide the leaf set into subsets of size 2 and $n - 2$. Clearly, $X_T' \leq X_T$. Moreover, the probability of the event $G$ that $T'$ shares a split with $T$ that is not of the type counted by $X_T'$ is bounded above by a term of order $n^{-1}$, and so (since $\mathbb{P}(X_T = X_T') \geq \mathbb{P}(X_T = X_T'|G)P(G) = 1 \cdot (1 - O(n^{-1})))$, we have

$$\mathbb{P}(X_T \neq X_T') = O(n^{-1}). \quad (14)$$

Now, for any two discrete random variables $X$ and $X'$, an elementary probability argument shows that

$$\sum_s |\mathbb{P}(X = s) - \mathbb{P}(X' = s)| \leq 2\mathbb{P}(X \neq X'),$$

and so

$$\sum_s |\mathbb{P}(X_T = s) - \mathbb{P}(X_T' = s)| \leq 2\mathbb{P}(X_T \neq X_T'). \quad (15)$$

Combining (14) and (15) gives

$$\sum_s |\mathbb{P}(X_T = s) - \mathbb{P}(X_T' = s)| = O(n^{-1}). \quad (16)$$

By the triangle inequality

$$\sum_{s \geq 0} |\mathbb{P}(X_T = s) - \mathbb{P}(Y_T = s)|$$

$$\leq \sum_{s \geq 0} |\mathbb{P}(X_T = s) - \mathbb{P}(X_T' = s)|$$

$$+ \sum_{s \geq 0} |\mathbb{P}(X_T' = s) - \mathbb{P}(Y_T = s)|,$$

which, combined with (16), gives

$$\sum_{s \geq 0} |\mathbb{P}(X_T = s) - \mathbb{P}(Y_T = s)|$$

$$\leq \sum_{s \geq 0} |\mathbb{P}(X_T' = s) - \mathbb{P}(Y_T = s)| + O(n^{-1}). \quad (18)$$

Thus, to establish Theorem 4, it suffices to show that

$$\sum_{s \geq 0} |\mathbb{P}(X_T' = s) - \mathbb{P}(Y_T = s)| = O(n^{-1}). \quad (19)$$

Now, by [10, Lemma 3], we have

$$\mathbb{P}(X_T' = s) = \sum_{r=s} \left[ (-1)^{r+s} \binom{r}{s} \right] \frac{c_T}{r} \frac{b(n-r)}{b(n)}.$$ \quad (20)

Furthermore, let $\lambda$ denote $\lambda_T$ for brevity, we have

$$\mathbb{P}(Y_T = s) = e^{-\lambda} \lambda^s/s! = \sum_{r=s} (-1)^{r+s} \binom{r}{s} \frac{\lambda^r}{r!}.$$ \quad (21)

Substituting this and (20) into the left-hand side of (19) gives the expression:

$$\sum_{s \geq 0} \sum_{r=s} (-1)^{r+s} \left[ \frac{c_T}{r} \frac{b(n-r)}{b(n)} - \frac{\lambda^r}{r!} \right].$$

which, after some algebra, and moving the absolute value inside the second summation, is bounded above by

$$\Delta_n := \sum_{s \geq 0} \sum_{r=s} \frac{1}{1} \frac{1}{(r-s)!} f(n,r), \quad (22)$$

where

$$f(n,r) := \left( \frac{c_T}{2n} \right)^r \frac{\prod_{i=1}^{r-1} (1 - i/c_T)}{\prod_{j=1}^{r} (1 - (2j + 3)/2n)} - 1.$$ \quad (23)

Using the fact that $c_T \leq n/2$ and a somewhat tedious case analysis, it can be shown that $f(n,r) \leq C/n$ for a constant $C$ that is independent of $r, n$. It follows that

$$\Delta_n \leq \sum_{s \geq 0} \sum_{r=s} \frac{1}{r!} \frac{1}{(r-s)!} C/n = Ce^2/n,$$

which establishes (19) and thereby the theorem. \hfill \square

Remark. If $T$ is selected uniformly at random from $BPT(n)$, then $\lambda_T$ converges in probability to $\frac{1}{2}$ by [5, Theorem 4(b)]. Thus, Theorem 4 can be viewed as a refinement of the main result from [10] that for two trees selected uniformly at random from $BPT(n)$ the number of nontrivial splits they share is asymptotically Poisson distributed with mean $\frac{1}{2}$.

4 APPLICATION TO LIKELIHOOD-BASED SUPERTREES

Steel and Rodrigo [12] recently presented a likelihood framework for constructing consensus trees and supertrees. Let $\mathcal{L}(T_i)$ denote the set of leaves of a (fully resolved) gene tree $T_i$. The probability of observing $T_i$ with leaf set $\mathcal{L}(T_i) = X_i$ given an estimated species tree or supertree $T$ has the form

$$\mathbb{P}_{T,X}(T_i) = \mathbb{P}_{T}(T_i) = \frac{1}{Z_{T|\mathcal{L}(T_i)}} e^{-\beta \delta(T,T_i|\mathcal{L}(T_i))}, \quad (23)$$

where $T|\mathcal{L}(T_i)$ denotes the restriction of $T$ to the leaf set $T_i$ and $\beta$ is a positive parameter that can be inferred by the data by maximum likelihood.

There are many reasons why an estimated gene tree might differ from the true tree, including sampling error, model violations, and alignment errors. Under the model of [12], the probability of observing a tree $T_i$ on a given leaf set $X_i$ falls off exponentially with its distance to the underlying tree $T$ restricted to $X_i$. The parameter $\beta$ can vary with the quantity and quality of the data, with high values of $\beta$ corresponding to more confidence in the gene tree estimates. See [2] for a recent discussion of this approach.

The normalizing constant

$$Z_{T_i} = \sum_{T|\mathcal{L}(T_i)} e^{-\beta \delta(T,T_i|\mathcal{L}(T_i))} \quad (24)$$

is required so that the $\mathbb{P}_{T}(T_i)$ values sum to 1 over all choices of $T_i$. One complication with this approach is that the normalizing functions $Z_{T_i}$ depend on $T$ (more precisely, although $Z_{T_i}$ does not depend on how the leaves of $T$ are labeled, it may depend on the shape of $T$), meaning that the constant needs to be computed in order to compare the likelihood values of two trees. This was overlooked in [12], in particular, Proposition 1 of that paper may only hold in certain cases (for example, if the sets $X_i$ are of size at most 5,
or if the \( \beta \) values are sufficiently large). However, [12, Proposition 1] can be corrected by replacing the term
\[
\sum_{i=1}^{k} \beta_i d(T, T^i | X_i)
\]
in the statement of that Proposition by
\[
\sum_{i=1}^{k} \beta_i d(T, T^i | X_i) + \gamma_i(T),
\]
where
\[
\gamma_i(T) = \sum_{i=1}^{k} \log(Z_{T_i}) = \log \left( 1 + \sum_{m=0}^{\infty} e^{-\beta m} n_m(T) \right),
\]
and \( n_m(T) \) is the number of fully resolved phylogenetic trees on leaf set \( X_i \) that have distance \( m \) from \( T^i | X_i \).

In general, normalizing constants are difficult to evaluate. When \( d \) is the Robinson-Foulds distance; however, computing the constant is straightforward. Suppose that \( |X_i| = n \) and \( b_m(T) \) has been computed for all \( m \). Then (suppressing the index \( i \)), we have
\[
Z_T = \sum_{T \in BPT(n)} e^{-\beta d(T, T')}
= \sum_{m} b_m(T) e^{-\beta m},
\]
which can be evaluated directly from the \( b_n(T) \) values, and thereby, in polynomial time overall in \( n \).

It is instructive to estimate \( Z_T \) in two limiting cases—first for values of \( \beta \) that are close to 0, and for values of \( \beta \) that are large. In both cases, we find that the dominant aspect of the shape of \( T \) affecting \( Z_T \) is the number \( c_T \) of cherries that \( T \) has. The experimental performance of these approximations is evaluated in the final section.

### 4.1 Small Values of \( \beta \)

Our first approximation for \( Z_T \) makes use of Theorem 4. Fix a tree \( T \) and, as before, let \( \lambda = c_T / 2n \), where \( c_T \) is the number of cherries in \( T \). Starting with (25), we have
\[
Z_T = \sum_{m} b_m(T) e^{-\beta m}
= b(n) \left( \sum_{s} q_s(T) \frac{e^{-2\beta(n-3-s)}}{b(n)} \right)
= b(n) \left( \sum_{s} \frac{e^{-\lambda s}}{s!} e^{-2\beta(n-3-s)} + O(n^{-1}) \right),
\]
this last line following from Theorem 4 and the inequality
\[
0 < e^{-2\beta(n-3-s)} \leq 1.
\]
Thus,
\[
Z_T = b(n) \left( e^{-2\beta(n-3)} \sum_{s} \frac{e^{-\lambda s}}{s!} e^{2\beta s} + O(n^{-1}) \right)
= b(n) \left( e^{-2\beta(n-3)} \lambda^{n-1} + O(n^{-1}) \right),
\]
giving the small-\( \beta \) approximation
\[
Z_T \approx b(n) \approx e^{-2\beta(n-3)} \lambda^{n-1}.
\]

Note that (27) makes use of the formula for the moment generating function of the Poisson distribution. For \( \beta \) close to 0, the identity \( e^{-\beta m} = 1 - \beta m + O(\beta^2) \) reveals that the difference between \( Z_T \) and the approximation
\[
b(n) \left( 1 - \beta \left( 2n - 6 - 2 \frac{c_T}{n} \right) \right)
\]
consists of terms of order \( \beta^2 \) and \( n^{-1} \). Thus, for \( n \) large, as \( \beta \) converges to 0, \( Z_T \) converges to a constant, and when \( \beta \) is close to 0, the small difference from this constant is dominated by \( c_T \).

### 4.2 Large Values of \( \beta \)

When \( \beta \) is large, let \( \epsilon = e^{-\beta} \). Then,
\[
Z_T = 1 + b_2(T) \epsilon + b_4(T) \epsilon^2 + O(\epsilon^3).
\]
Now, \( b_2(T) = 2(n - 3) \), and from [11, Theorem 2.26], we have
\[
b_4(T) = 4 \left( \frac{n - 3}{2} \right) + 6(n - 6 + c_T).
\]
Thus, if we let \( A_n := 1 + (2n - 3) \epsilon + 2(n^2 - 4n - 6) \epsilon^2 \), then
\[
Z_T = A_n + 6c_T \epsilon^2 + O(\epsilon^3),
\]
giving the large-\( \beta \) approximation
\[
Z_T \approx A_n + 6c_T \epsilon^2.
\]
Once again, we see that in the limit (in this case, as \( \beta \) tends to infinity), \( Z_T \) converges to a constant, and for large values of \( \beta \), the small difference from this constant is dominated by \( c_T \).

### 5 EXPERIMENTAL RESULTS

#### 5.1 Features of Distribution

To study general features of the distribution and examine the accuracy of the above approximations, we generated random trees and computed the distribution of the Robinson-Foulds distance for each tree. The trees were drawn from a uniform distribution, with the number of taxa varying from 5 to 50. One thousand replicates were performed for each number of taxa. We also constructed an unrooted caterpillar tree and a balanced unrooted tree for every set of taxa. A balanced unrooted tree is one that minimizes the length of the longest path between any two leaves, an example being the right-hand tree in Fig. 1.

As predicted from the Poisson approximation, the distributions of Robinson-Foulds distances from a fixed tree were highly peaked. For all of the trees examined, at least 99 percent of trees are either at distance \( 2(n - 3) \), the maximum possible, or distance \( 2(n - 4) \).

For \( T \in BPT(n) \), let \( N_k(T) \) denote the number of trees in \( BPT(n) \) within Robinson-Foulds distance \( k \) of \( T \): that is,
\[
N_k(T) = \sum_{m=0}^{k} b_m(T).
\]
Then, \( N_2(T) = 2(n - 3) + 1 \), the number of trees that share all but one split with \( T \), together with the tree \( T \) itself. When \( k > 2 \), the value of \( N_k(T) \) varies with the shape of \( T \). We observed that for all \( k \), \( N_k(T) \) was minimized when \( T \) is a
caterpillar. At the other extreme, \( N_2(T) \) was almost always maximized when \( T \) was balanced, the exception being when \( T \) was balanced but did not have the maximum number of cherries.

5.2 Accuracy of Approximations

For each tree and a range of different values for \( \beta \), we computed the exact normalizing constant \( Z_T \). Fig. 2 illustrates the variation in \( Z_T \) over different values of \( \beta \), displayed on a log-log plot. The central curve gives the average \( Z_T \) values for 1,000 fifty taxa trees drawn from a uniform distribution, as a function of \( \beta \). The small- and large-\( \beta \) approximate values for \( Z_T \) are also plotted.

As a function of \( \beta \), the normalizing constant has two distinct phases. The small-\( \beta \) approximation fits well for \( \log(\beta) < 0.2 \) (approximately), while the large-\( \beta \) approximation fits well for \( \log(\beta) > 0.2 \). By differentiating, we see that the small-\( \beta \) approximation has a minimum at \( \beta = \frac{1}{2} \log\left(\frac{n}{3}\right) \). To the left of this minimum, the curve is well fitted by the maximum of the two approximations. To the right of this minimum, the large-\( \beta \) approximation is best. To summarize, let \( C_T \) be the number of cherries of \( T \), \( \lambda = C_T / 2n \), \( \epsilon = e^{-2\beta} \), and \( A_{n, \epsilon} := 1 + (2n - 3)\epsilon + 2(n^2 - 4n - 6)\epsilon^2 \). We then have the approximation

\[
Z_T \approx \begin{cases} 
\max \{ b(n) (e^{-2\beta(n-3)} + \lambda (e^{2\epsilon} - 1)) \}, & \text{if } \beta < \frac{1}{2} \log\left(\frac{n-3}{\lambda}\right), \\
A_{n, \epsilon} + 6C_T \epsilon^2 & \text{otherwise.}
\end{cases}
\]

5.3 Importance of Normalizing Constant

As we observed above, to correctly compute the likelihood for a supertree under the model of [12], we need to compute \( Z_T \) for every distinct supertree \( T \). Even though, this calculation takes polynomial time, it is still extremely expensive computationally, particularly considering that millions of candidate supertrees may be considered. Here we examine whether or not this computation is strictly necessary. If we ignore the normalizing constant when comparing likelihoods, would the relative likelihood ordering of distinct trees change? The key question is to determine how much the normalization constants \( Z_T \) vary. If the difference is sufficiently small, then there will be no impact from ignoring the differences between normalizing constants.

For a given value of \( \beta \), define the range of \( Z_T \) to be the ratio of the largest to the smallest \( Z_T \) values over all fully resolved trees with \( n \) taxa. Fig. 3 plots the range of \( Z_T \) for the values of \( \beta \) used in Fig. 2, and for \( n = 10, 20, 30, 40, 50 \) taxa trees, on a log-log axis. The trees minimizing \( Z_T \) were always caterpillar trees and the trees maximizing \( Z_T \) were usually, but not always, balanced trees. Fig. 3 indicates that when \( \beta \) is outside the range [0.03, 3], there is little variation in \( Z_T \) between different trees. With 50 taxa, the normalizing constants differ by a maximum of 7.5 log units.

Suppose that we are comparing the log-likelihood of two trees \( T_1 \) and \( T_2 \) with respect to a third tree \( T \). If \( d_{RF}(T, T_1) \neq d_{RF}(T, T_2) \), then

\[
\left| \log (e^{-\beta d(T, T_1)}) - \log (e^{-\beta d(T, T_2)}) \right| \geq 2\beta,
\]

so ignoring the normalizing constant will only change the ordering of the likelihood values if \( \log Z_{T_1} - \log Z_{T_2} \geq 2\beta \). Plotting the curve for \( 2\beta \) on Fig. 3, we see that \( \log Z_{T_1} - \log Z_{T_2} \geq 2\beta \) for some pairs of 50 taxa trees only when \( \beta \) lies in the interval [1.25, 1.86]. The corresponding interval will be even smaller for trees with fewer taxa: for 20 taxa trees, there is no value of \( \beta \) for which ignoring \( Z_T \) scores leads to a switch in the order of likelihood values for two trees.

In summary, when \( \beta \) is approximately 1.5 and the number of taxa is greater than around 20, it is potentially important to correctly compute normalization constants. Outside that range, the influence of \( Z_T \) on likelihood rankings can be safely ignored. We note, however, that here,
we are only interested in relative ordering of supertrees with respect to likelihood: a Bayesian Monte-Carlo approach may well need accurate $Z_T$ values for all $\beta$.

ACKNOWLEDGMENTS

The authors thank the three anonymous referees for their helpful comments, particularly for the suggestion to use the Poisson approximation directly when deriving small $\beta$ approximations for $Z_T$. They also thank the Alexander von Humboldt Foundation and the Marsden Fund (DB) for supporting this work.
